Abstract

Invasive plants directly and indirectly disrupt the ecosystem functioning, of which indirect effects, for example, through trophic cascades, are particularly difficult to predict. It is frequently assumed that the impact of an invading species on the ecosystem is proportional (linearly related) to its density or abundance in a habitat, but this assumption has rarely been tested. We hypothesised that abundance and richness of plants and potentially pollinators of wet meadows change as a result of invasion of steppleshrub *Spiraea tomentosa* and that these changes are proportional to the density of the shrub. We selected 27 sites amongst wet meadows habitats invaded by *S. tomentosa* with coverage ranging from 0% to 100% and examined the diversity of plants, as well as the abundance and diversity of flower visitors (bees, butterflies with moths and flies). Our results showed that the richness of plants, as well as the richness and number of individuals of flower visitors, decrease significantly and linearly with an increase of the *S. tomentosa* cover. This finding supports the hypothesis that the impact of an invasive species can be proportional to their population density, especially if this species is limiting the available resources without supplying others. Our study is the first to show such an unequivocal negative, linear effect of an invasive shrub on the abundance

and richness of potential pollinators. It proves that the negative impact of *S. tomentosa* on the wetland ecosystem appears even with a minor coverage of the invader, which should be taken into account when planning activities aimed at controlling the population of this transformer species. The simultaneously detected linear dependence allows us to assume that the benefits of controlling secondary populations of the shrub can be proportional to the incurred effort.

Introduction

Freshwater wetlands are important refuges for hygrophilous and hygrobiont plants and animals and, as such, they support diverse and unique species assemblages (Burke and Gibbons 1995). Nevertheless, in spite of the ecosystem services they provide, these types of ecosystems have been lost, degraded or strongly modified by human activities worldwide (Moroń et al. 2008; Davidson 2014; Reis et al. 2017). One of the most important reasons for their degradation are biological invasions, to which these ecosystems seem to be especially vulnerable (Zedler and Kercher 2004) due to frequent, large-scale disturbances, influx of nutrients, runoff of propagules flowing down the ground and accumulating in land depressions, as well as their limited connection over the network of corridors (Zedler and Kercher 2004; Fletcher et al. 2019). Invasive plants disrupt the functioning of wetland ecosystems at different levels of their organisation both directly, for example, through competition for resources or changes in habitat conditions and indirectly, for example, through the trophic levels (Dibble et al. 2013; Mazurczyk and Brooks 2021). By initiating food chains, these plants can affect trophic interactions (Pearson 2009), which may initiate a trophic cascade (López-Núñez et al. 2017) manifested in population changes of consumers caused by direct and indirect relationships between them.

Amongst animals, insects are a group particularly sensitive to disturbances resulting from plant invasions (Van Hengstum et al. 2014; Schirmel et al. 2016), because they are highly dependent on plants as sources of food (Ehrlich and Raven 1964; Coley et al. 2006), shelter and breeding ground (Spafford et al. 2013). Therefore, the magnitude of response to changes in native flora composition caused by invasive plants varies extremely in different guilds of insects (Moragues and Traveset 2005; Fenesi et al. 2015). One of the crucial functions insects play in the ecosystem is pollination (Klein et al. 2007), which is the key in maintaining plant species diversity (Potts et al. 2010). However, data on the impact of invasive plants on pollinator populations are still scarce, whereas the effect of invasive plants on a pollinator community is equivocal (Bjerknes et al. 2007). Invasive plant species often compete with native ones for ecosystem services, such as pollination (Moragues and Traveset 2005; Larson et al. 2006; Bjerknes et al. 2007; Dietzsch et al. 2011; Williams et al. 2011). There are also known cases of pistil stigmas of native species being blocked by deposited foreign pollen,

which may limit the reproductive success of native plants (Brown et al. 2002; Larson et al. 2006). Nevertheless, invasive plants, due to their higher level of generalisation with regard to pollinators when compared to native plants, may also play new, important topological roles. For example, they attract pollinators to visit invaded ecosystems (Albrecht et al. 2014), increase the frequency of visits of pollinators on flowers of plants found in the same habitat (Bartomeus et al. 2008), increase pollinator populations, flight frequency and range (Moragues and Traveset 2005) and fill the seasonal resource gap in the native flora (Tepedino et al. 2008).

The direction of the impact of invasive plants on pollinators is strongly dependent on the scale of the invasion (Powell et al. 2013; Rejmánek and Stohlgren 2015). It is often assumed that the impact of invasive plants is proportional to their population density (Yokomizo et al. 2009; Elgersma and Ehrenfeld 2011; Panetta and Gooden 2017), but, as noted by Elgersma and Ehrenfeld (2011), this assumption has been rarely tested and there is ample evidence that the effects of plant invasions on native pollinators are not linear (Moroń et al. 2019). Thus, the question arises whether the scenario of the non-linear effect of invaders on native plants and pollinators is a more general pattern. Therefore, in this study we assessed the impact of steeplebush on the species diversity of vascular plants, as well as the species number and diversity of pollinators in wet meadows.

The North American steeplebush (*Spiraea tomentosa* L., Rosaceae) is a highly invasive shrub found in central and northern Europe (Dajdok et al. 2011), with high potential for further spread (Wiatrowska et al. 2020). In the area of its natural occurrence, in the southern United States (USDA – The Plants Database 2022), *S. tomentosa* grows especially in wetland habitats and enters transitional and raised bogs (Reschke 1990; Schafale and Weakley 1990; Faber-Langendoen 2001). According to LaRosa et al. (2004), in its natural range, the shrub offers pollen and nectar as a reward for pollinators and, depending on the population density, it may have different (opposing) impacts on pollinators, such as bees (bumblebees) included in this study.

In Europe, *S. tomentosa* has been cultivated as an ornamental plant since the 18th century (Symes 1983). Currently this shrub is found in nine countries: Sweden, Germany, Poland, Belgium, Denmark, Norway, Croatia, Romania and Great Britain (Dajdok et al. 2011; GBIF 2022), while it is considered as an invasive species in five countries: Belgium (Invasive species of Belgium 2022), Denmark (Bruus et al. 2007), Germany (Balkenhol et al. 2018), Sweden (Tyler et al. 2015) and Poland (Dajdok et al. 2011; Tokarska-Guzik et al. 2012). In the area of its secondary occurrence, this shrub forms monodominant plant stands completely changing the structure and plant species composition of wetland communities – wet grasslands, lowland peat bogs or marsh forests (Dajdok et al. 2011; Wiatrowska and Danielewicz 2016) (Fig. 1).

However, still very little information is available on its effects on pollinators – flower visitors and the plant species composition. These data are urgently needed to communicate management priorities in times when invasions are a threat and challenge in nature conservation (Pyšek et al. 2020; Ricciardi et al. 2021; Moodley et al. 2022).

Spiraea tomentosa interacts with pollinators (LaRosa et al. 2004) and meets all four conditions (flower attraction, taxonomic affinity to native plants, formation of

dense populations and generalised pollination strategy) that, according to Bjerknes et al. (2007), make alien plants strong interactors for pollination in the area of their secondary range. The shrub was brought to Europe (Symes 1983; Hardtke and Ihl 2000) because it has stately inflorescences (Dajdok et al. 2011) that can be attractive to pollinators (Chittka and Schürkens 2001; Brown et al. 2002). The plant has a taxonomic affinity to *S. salicifolia* L. (Mirek et al. 2002) native to Central Europe, as well as many other *Spiraea* spp. common in cultivation (e.g. *S. douglasii* Hook. or *S. \times pseudosalicifolia* Silverside), which may facilitate attracting pollinators. Moreover, *S. tomentosa* develops denser and larger populations (Wiatrowska and Danielewicz 2016) than other species known as particularly attractive to pollinators (Ågren 1996; Mustajärvi et al. 2001; Thompson 2001). Probably, due to the relatively simple structure of flowers (*S. tomentosa* flowers are bisexual, 0.5–1.5 mm in diameter, with five free sepals, five petals orbiculate, free, usually light pink, five carpels and 15–20 stamens (Flora of North America 2022)), it also has a generalised pollination strategy, which means that it can attract many groups of pollinators.

Based on these premises, our main goal was to assess whether there was a relationship between the abundance of *S. tomentosa* and the diversity of plants, as well as the abundance and diversity of potential pollinators in wet meadow communities. We considered what influence the invader – non-linear or linear – has on plants and potential pollinators of indigenous communities. In the case of a non-linear relationship, the question arises whether there is a certain minimum point (tipping point), at which a pollinator population changes as the invasive plant becomes dominant.

We tested the hypotheses that: (1) the richness of plants and the abundance and richness of visiting pollinators change as a result of *Spiraea tomentosa* invasion and (2) changes are proportional (linearly) to the density of the shrub. The implementation of these studies was essential to provide insight into the density-dependent impact of the invasive alien species *S. tomentosa* on biodiversity, focusing on plants and pollinator species.

Methods

Study area

The research was carried out in a wet meadow complex located in the Lower Silesian Forests, in south-western Poland, where one of the first documented observations of *S. tomentosa* naturalisation in Europe was made (Fiek 1881; Schube 1903). Based on the water table (Bieroński et al. 2000a, b) and the present vegetation maps (Forest Data Bank 2022), we prepared distribution maps for wet meadows, where the soil is periodically saturated with water. The meadows are located in the same physical and geographic division (the Lower Silesian Forests mesoregion) (Solon et al. 2018) and have a similar geological history (Rzechowski 1994), climate (Woś 1999), soil properties and moisture conditions – the groundwater table is located just below the soil surface (Forest Data Bank 2022).

In the Lower Silesian Forests from the 1890s, large-scale drainage works were carried out, but after the Second World War, the maintenance of hydrotechnical structures was abandoned, which resulted in secondary bogging of the area (Bieroński et al. 2000a, b). Nowadays wet meadows are mainly maintained by regular management schemes, but *S. tomentosa* is spreading in many places (Wiatrowska and Danielewicz 2016). All studied meadows are dominated by *Molinia caerulea* (L.) Moench and *Juncus effusus* L. with numerous other native plants (Rutkowski 2011) suitable for pollinators (e.g. *Lythrum salicaria* L., *Lotus uliginosus* Schkuhr, *Cirsium palustre* (L.) Scop., *Filipendula ulmaria* (L.) Maxim., *Galium palustre* L., *Potentilla erecta* (L.) Raeusch, *P. reptans* L. or *Linaria vulgaris* Mill.) (Bělin 1999; Buszko and Masłowski 2008).

In 2021, amongst six wet meadow complexes, 27 study sites were randomly selected for further analyses, each characterised with different *S. tomentosa* coverage. Wet meadows were at least 5000 ± 620 m apart, while the study sites located in the same meadow, but differing in *S. tomentosa* density, were at least 60 ± 42 m apart. To control the disruptive effects of the potential spatial gradients (distance from forests, human settlements, farmlands and meadows), we applied the Spearman test to make sure that these features did not correlate with steeplebush cover. We ensured that the selected study sites do not correlate with the distance of places to the closest forest areas (woodlands) ($r_s = -0.08$, $p = 0.703$), human settlements ($r_s = 0.36$, $p = 0.069$), farmland ($r_s = 0.04$, $p = 0.844$) and meadows ($r_s = 0.14$, $p = 0.461$). The distances were measured with QGIS 3.16 (QGIS Development Team 2022).

Surveys

In each of the study sites ($n = 27$), permanent circular plots of 100 m^2 were established. On each of these sites, the *S. tomentosa* cover was determined, a list of vascular plants was made and flower visitors were caught using a pan-trap placed in their centre. Data were collected during the period of full flowering of the shrub (Wiatrowska et al. 2018a) – in the second half of July and in August 2021.

The estimation of *S. tomentosa* coverage in the study sites was performed between 18 and 20 July 2021. Shrub cover was estimated visually using a cover class method (a modified Braun-Blanquet method) (Kercher et al. 2003), which provided reliable estimates for the dominant shrubs (Floyd and Anderson 1987). The coverage was estimated in classes with an accuracy of 10%, or less (every 0.5%), in the case of very low shrub densities (< 10%). The estimation consisted in an evaluation of what part of the study site is covered by all above-ground steepplebush organs jointly (e.g. shoots, leaves, flowers, fruits) by projecting them vertically on to the plane surface of the tested site. On all of the study sites, *S. tomentosa* cover ranged from 0% to 100% ($47.6 \pm 36.2\%$; mean \pm SD) (see Appendix 1), where meadows completely free of the invasive shrub were taken as controls (0% invader coverage).

The plants species composition was surveyed twice (18–20 July and 27–29 August 2021) at each study site ($n = 27$) located in wet meadows at permanent circular plots (100 m²). The vast majority of plant communities consisted of native species (74). However, in addition to *S. tomentosa*, the presence of single seedlings or juveniles of five other alien species was found (seedlings of *Prunus cerasifera*, *P. serotina*, *Quercus rubra* and juvenile of *Solidago canadensis* and *Juncus tenuis*). All the identified plant species, including *S. tomentosa*, were included in the analysis. Due to the fact that alien species other than *S. tomentosa* did not bloom during the field study, their presence was found on single sites and all had a negligible coverage (< 1%), thus it was assumed that they had no effect on flower visitors. Additionally, there was no relationship between *S. tomentosa* cover and the number of non-native species (generalised linear mixed-effects models; $t = -0.513$, $R^2 = 0.01$, $p = 0.618$). All plants were identified according to Rutkowski (2011).

Pan traps to catch insects ($n = 27$) were set up in the central part of each of the 27 study sites. This type of trap was used because they are an effective method of trapping insects in semi-natural habitats, including open areas with a wider field of vision (Mazon and Bordera 2008; Westphal et al. 2008; Acharya et al. 2021). Despite the limitations of the pan-trap method (Westphal et al. 2008; O'Connor et al. 2019), caused amongst others by their varying effectiveness in catching different groups of insects (Vrdoljak and Samways 2012), widely discussed perception of colour by insects (Briscoe and Chittka 2001; Song and Lee 2018; Van Der Kooi et al. 2021), including the colour of traps (Campbell and Hanula 2007; Vrdoljak and Samways 2012; Acharya et al. 2021), this method shows relevant effectiveness (O'Connor et al. 2019). Pan traps are useful for species that are active at night, trapping also rare or scarcely represented species. Their permanent presence in the field regardless of the temperature changes during daytime is of particular importance to obtain data on the complete species community, including specific weather conditions, during which, for example, bee flights take place (Borański 2015). According to premises presented above, one type of unicoloured, white traps were used to catch insects spontaneously attracted by the flowers of *S. tomentosa*. White pan traps are also commonly used in research on flower-visiting insects (Disney and Erzinclioglu 1982; Banaszak et al. 1994; Duelli et al. 1999; Campbell and Hanula 2007; Westphal et al. 2008; Vrdoljak and Samways 2012).

The traps were positioned in sunny places, on poles at the height of *S. tomentosa* inflorescences (ca. 70 cm above the ground and approx. 10 cm from the inflorescences of the shrub). The traps were 15 cm in diameter and filled to 2/3 volume with a mixture of water (95%), ethylene glycol (4.8%) and detergent (0.2%). Traps were first installed on 21 July 2021 and inspected three times at 14-day intervals during the peak of flowering and the peak of pollen season of this species. The samples were collected 03, 17 and 31 of August (exposure 21 July–03 August, 04 August–17 August, 18 August–31 August 2021), which made a total of 81 samples (pan traps). The caught insects were poured through a strainer and preserved in test tubes with 75% ethyl alcohol. Each selected group of flower visitors was identified according to Dathe (1980); Schmid-Egger and Scheuchl (1997); Pesenko et al. (2000); Pawlikowski and Celary (2003); Celary (2005); Scheuchl (2006); Bogusch and Straka (2012) – bees Apoidea Hymenoptera, Karsholt and Rązowski (1996) – butterflies and moths Lepidoptera, Speight (2017) – flies Diptera.

Statistical analysis

All data analyses and visualisations were performed using the R ver. 4.2.1 software (R Development Core Team 2022). To verify the number of individuals and the species richness of potential pollinators, as well as plant species richness depending on *S. tomentosa* cover, we used the generalised linear mixed-effects models (GLMM) with a negative binomial distribution (bee abundance and species richness; butterfly and moth abundance and species richness, fly abundance) or Gaussian distribution (fly species richness, plant species richness) with the study meadow and site identities as the nested random factors. The models' assumptions were verified using the DHARMA ver. 0.4.6 package (Hartig and Lohse 2022). Additionally, models and results were provided applying GGEFFECTS ver. 1.1.4 (Lüdecke 2022), LME4 ver. 1.1-31 (Bates et al. 2022), LMERTTEST ver. 3.3 (Kuznetsova et al. 2022) and MUMIN ver. 1.47.1 (Bartoń 2022) packages. The visualisations were performed using GGPlot2 ver. 3.4.0 package (Wickham et al. 2022).

In addition, to understand if possible differences in the composition of potential pollinator communities depending on *S. tomentosa* cover are caused by pollinator species replacement or loss, we calculated the mean rank of the samples in a maximally packed matrix for overall pollinators: nestedness means that species-poor sites (i.e. those with a high rank in the nested matrix) are subsets of species-rich sites (those with a low rank). Data analyses and visualisation were performed using BIPARTITE ver. 2.18 (Dormann et al. 2022) and VEGAN ver. 2.6-4 (Oksanen et al. 2022) packages.

We compared the rank of samples in the maximally packed matrix with GLMM (Gaussian distribution with the meadow and site identities as the nested random factors). The models' assumptions were verified using the DHARMA ver. 0.4.6 package (Hartig and Lohse 2022). Additionally, to obtain the models and results, we used GGEFFECTS ver. 1.1.4 (Lüdecke 2022), LME4 ver. 1.1-31 (Bates et al. 2022), LMERTTEST ver. 3.3 (Kuznetsova et al. 2022) and MUMIN ver. 1.47.1 (Bartoń 2022) packages. The visualisations were performed using GGPlot2 ver. 3.4.0 package (Wickham et al. 2022).

Results

During overall 27 216 hours of the pan-trap deployment, we collected 3649 individuals of 191 potential pollinator species or families (in the case of flies). Flies (Diptera) formed the most abundant pollinator group, accounting for 75% of all trapped insects. Butterflies and moths (Lepidoptera) comprised 15% of the collected insects. Bees (Apoidea, Hymenoptera) were only a minor fraction of flower visitors (10% of the specimens). A total of 80 vascular plant species were recorded in the investigated study sites (Table 1).

A negative relationship was found between steplebush cover and plant species richness ($t = -7.15$; Fig. 2), with a 60% decrease of plant species richness.

An increase in *S. tomentosa* cover correlated also with a decline in the number of bee, butterfly and moth and fly individuals by about 70%, 80% and 45% (Fig. 3A–C), respectively (bees: $Z = -4.77$; butterflies and moths: $Z = -7.54$; flies: $Z = -2.81$). Similarly, bee, butterfly (and moth) and fly species richness decreased across the range of *S. tomentosa* cover by approx. 70%, 70% and 30% (Fig. 3D–E), respectively (bees: $Z = -4.35$; butterflies and moths: $Z = -6.22$; flies: $t = -2.46$).

The potential pollinator community in the habitats studied was significantly nested, indicating that species-poor samples (pan traps with a high rank) constituted subsets of species-rich samples (pan traps with a low rank) and that this pattern was not random. The nestedness rank significantly increased in proportion to *S. tomentosa* cover ($t = 6.40$; Fig. 4; see Appendix 2).

Figure 2. The relationship between species richness of plants and site cover by *Spiraea tomentosa*. Points represent each of 27 sites. Point colours correspond to a meadow. The 95% CI are marked with polygons. Jittering was added to aid visualisation.

Discussion

The direction (negative vs. positive), the shape (linear vs. non-linear) and the strength of the relationship between the abundance of the invasive species and the diversity of native species determine which invaders pose the greatest threat to ecosystems (Bradley et al. 2019). It is often indicated that the impact of some invading species is proportional (linearly related) to its density or abundance in a habitat (Yokomizo et al. 2009; Elgersma and Ehrenfeld 2011; Panetta and Gooden 2017; Sofaer et al. 2018), but there is also much evidence that the impact of other invaders may elicit a non-linear response from native species (Elgersma and Ehrenfeld 2011; Panetta and Gooden 2017; Moroń et al. 2019).

In our research, we found a strong, negative, linear impact of the *Spiraea tomentosa* cover on vascular plant species richness, so this result positively validates the hypothesis. Our results showed that the diversity of plants decreased due to the increased invasive shrub coverage. These results correspond with a global meta-analysis that assessed the direction, shape and strength of the response of native communities to the increasing abundance of invasive species (Bradley et al. 2019). It was found that most often the impacts of invasive plants on native plant communities (at the same trophic level) are significantly negative and linear. However, the average impact of invasive plants on the diversity of native plants, estimated at 28% (Bradley et al. 2019), is much smaller than that shown for *S. tomentosa* in our research (60%).

In other studies on the impact of alien species on plant species richness, it was found that, amongst alien species entering wetlands in Central Europe, the invasion of *Mimulus guttatus* DC and *Impatiens glandulifera* Royle does not reduce the species richness of native plants. The invasion of *Solidago gigantea* Aiton and *Rudbeckia laciniata* L. decreases species richness by about 26% and 30%, while the invasion of *Fallopia sachalinensis* (F. Schmidt) Ronse Decraene, *F. japonica* (Houtt.) Ronse

Decraene and *F. ×bohemica* (Chrtek & Chrtková) JP Bailey contributes to the reduction of species richness by 86%, 73% and 66%, respectively (Hejda et al. 2009). Amongst the species entering wetlands, the impact of *S. tomentosa* on plants is, therefore, comparable to the impact of alien *Fallopia* sp. considered as an example of transformer species (Sukopp and Sukopp 1988; Cronk and Fuller 1995; Sukopp and Starfinger 1995), which changes the nature, condition and form or character of ecosystems (Richardson et al. 2000).

The direction, shape (linear vs. non-linear) and strength of the impact of an invasive plant species on insects, including potential pollinators, is more difficult to predict (Stout and Morales 2009; Lenda et al. 2010). When invasive species are at a lower trophic level, no consistent trend of impacts on native species or communities has been demonstrated (Bradley et al. 2019). This is due to the properties of environments that have different buffering potentials, for example, due to the condition of the recipient's native ecosystem (e.g. Mason and French (2007); Pyšek et al. (2012)), different redundancy of the food web (Gilbert and Levine 2013), as well as properties of the invasive species themselves. The role of the invasive species impact on pollinator assemblages is ambivalent – some of them increase the base for pollinators (Moragues and Traveset 2005; Bartomeus et al. 2008; Hejda et al. 2009; Stout and Morales 2009), while others may limit it (Vanbergen et al. 2018). Reducing plant diversity is considered to be a factor that is directly manifested in reduced food resources for pollinating insects (Potts et al. 2003; Morón et al. 2008; Senapathi et al. 2015, 2017), but, as noted by Vanbergen et al. (2018), surprisingly little research unequivocally indicates the negative impact of invasive species on the diversity or abundance of pollinators.

In our research, we found a strong, negative, linear influence of *S. tomentosa* on the abundance and diversity of flower visitors, which allows us to positively verify our hypothesis regarding the negative effect of the shrub cover on potential pollinators.

Butterflies and moths seem to be least resistant to *S. tomentosa* infestation, as in dense populations of this shrub, the number of individuals decreased by 80% and species richness was reduced by 70%. The strong response of this group of insects is understandable, because Lepidoptera species strongly depend on plants throughout their life cycle – they use them for breeding and as a source of food for larvae and adults (Altermatt and Pearse 2011), resulting in their limited resistance to disturbance. Butterflies and moths have been shown to suffer from invasion, because alien plant species can replace beneficial native partners (Lenda et al. 2013; Trigos-Peral et al. 2018) and many butterfly species are recognised as food specialists, functionally constrained to exploiting a limited group of plants (Tallamy and Shropshire 2009), for which food source redundancy is relatively low (Morón et al. 2019). Moreover, invasive plants due to their low nutritional value or toxicity may reduce their reproductive success and consequently lead to genetic bottlenecks (Davis and Cipollini 2014). Some of these plants can also affect the herbivores to become more attractive to predators (Bezemer et al. 2014). Although shoots and leaves of *S. tomentosa* can be used as a food source by a native moth species – *Earias clorana* larvae (Wiatrowska et al. 2018b), our results indicate that the buffering mechanism is not observed and butterflies, as well as moths, react quickly and very negatively to *S. tomentosa* invasion.

Other insects that have strong, often reciprocal, relationships with native species of flowering plants include bees. Pollinator bees are very sensitive to a particular diet source and combination of nutrients (Harmon-Threatt and Kremen 2015), such as the ratio of various essential amino acids (EAA) to carbohydrates and show poor growth and survival when reared on monotype or non-optimal nutrition diets (Vanbergen et al. 2018). It was found that the protein content of pollen varies with the plant species (Roulston et al. 2000), which influences the pollen-feeding behaviour of bees (Cook et al. 2003; Keller et al. 2005). The reduction or elimination of specialised partner plant populations is particularly important for certain solitary bee species that have specialised relationships with flowering plants (Mueller and Kuhlmann 2008). It is also known that even generalist bee species (which often benefit from abundant resources of mass-flowering invasive plants; Stout and Morales (2009)) require diverse sources of floral pollen, because pollen from different plant species varies in digestibility and nutrient content (Roulston et al. 2000). In our research, we found that bees are almost as sensitive to *S. tomentosa* invasion as butterflies. In dense populations of the shrub, a reduction in the number of bees by 60% was recorded and bee species richness decreased by 70%, which indicates that *S. tomentosa*, despite the large supply of pollen, which constitutes the majority of bee nutrition (Stout and Morales 2009), seems not to be attractive for this group of insects. It is worth noting that the response of bee populations to the presence of *S. tomentosa* in the ecosystem seems to be different in the area of the natural occurrence of the shrub and outside it. In North America, *S. tomentosa* offers both pollen and nectar as pollinator rewards and it is recognised as a species that attracts bumblebees (LaRosa et al. 2004). In Europe, the shrub provides only pollen, which may reduce its attraction to flower visitors looking for nectar. The differences between resources provided by *S. tomentosa* flowers in its native range and in invaded areas may be a result of the pollinator density differences between these areas (Muñoz and Cavieres 2008) or the lack of adaptation to obtaining flower reward (e.g. Liu and Pemberton 2009). However, the latter is unlikely in the case of *S. tomentosa* flowers, which are morphologically similar to flowers of other *Spiraea* species that naturally occur in Central Europe (Mirek et al. 2002).

Another important order amongst insects pollinating flowers around the world are flies from the Syrphidae, Bombyliidae and Muscoidea families (Larson et al. 2001), but also other erroneously overlooked Diptera pollinators (Ssymank et al. 2008; Orford et al. 2015). Amongst all the studied groups of pollinators, flies are the least specialised in flowers, because even though they use pollen and nectar, they also use other food sources (Brock 2015). Additionally, for this group of potential pollinators, a negative effect of *S. tomentosa* coverage on their number and diversity was revealed, but with the lowest impact. In dense populations of this shrub, a reduction in the number of individuals by 45% and reduction in species richness by 30% were found, which may result from the lowest dependence on a specific food source, but also from their greatest mobility amongst the studied groups of insects (Van Veen 2004). Unlike bees, whose females build nests for their offspring and are associated with them because they procure larval cells in the nest, expand it and sleep in it (Batra 1984), many flies have great power of dispersal spread and they are found far from their site of development (Ssymank 2001; Van Veen 2004).

For all the studied groups of potential pollinators, it was found that the influence of *S. tomentosa* is proportional to its density coverage. The number of individuals and richness of butterflies and moths, bees and flies significantly, linearly decreased with the increase in the steeplebush cover, which supports the thesis that the impact, at least of some invasive plants, is proportional to invader population density (Yokomizo et al. 2009; Elgersma and Ehrenfeld 2011; Panetta and Gooden 2017). Moreover, the potential pollinator community assemblages seem to be affected as *S. tomentosa* cover increases (Fig. 4). Changes in the community assemblages are a result of species loss rather than the constitution of new communities by species replacement. Thus, in areas highly impacted by invasive steeplebush, only a part of the original pool of species can persist. The next step should be to identify traits which make some species less vulnerable to biological invasions (Moroń et al. 2021).

Most studies indicate that the impact of invasive species on potential pollinators depends on whether the invasive species reduces resources, upon which the native species depends and also whether it acts as a novel resource for the native species (Bradley et al. 2019). In the case of the goldenrod (*Solidago canadensis*) invasion, it has been found that this plant reduces the resources, on which native pollinator species depend (it has a linear negative effect on plants). At the same time, it is also a food source for some butterflies and bees (Fenesi et al. 2015), which can cause a buffering effect and result in a non-linear plant impact on pollinators (Moroń et al. 2019). In the case of *S. tomentosa*, we found that this shrub is highly competitive with native plant species and displaces species of wet meadows, which reduces the resources available to native pollinators. Moreover, despite the large supply of pollen steeplebush is not attractive for most pollinators (Wiatrowska et al. 2018a), it does not have compensating properties that would buffer the displacement of native species, which is manifested in a strong, negative, linear response of potential pollinators to *S. tomentosa* invasion.

Conclusions

Effective nature conservation and management of invasive plant species should be based on a comprehensive understanding of the role they play in our ecosystems (Barney 2016). We found that *S. tomentosa* invasion in the wetland ecosystem has a very strong negative effect on the populations of plants and potential pollinators. In the areas invaded by this shrub, only a small part of the native species pool may persist, which implies that *S. tomentosa* should be considered as a transformer species.

The number and diversity of plants, butterflies and moths, bees and flies change at all points in the *S. tomentosa* invasion pathway (representing a linear response to invasion). Although it was assumed that invasive plant impacts are highly scale-dependent (Powell et al. 2013; Rejmánek and Stohlgren 2015), our study is the first to show such an unequivocal negative, linear effect of an invasive species impact on the abundance and diversity of potential pollinators.

Many studies showed that the management effort in the case of invasive species populations largely depends on the density–impact curve of the species and optimisation of management relies on minimising the sum of the costs of their impact and management (Yokomizo et al. 2009). For a linear effect of *S. tomentosa* on plants and potential pollinators, it can be expected that the benefits of controlling this plant will be proportional to the effort involved. As the strong negative impact of this shrub population is observed even at a small density of its population, the control of this plant population at the initial stage of invasion, before its indiscriminate spreading, seems to be the best and most promising approach.
